Who was Impacted and How? Covid-19 Pandemic and the Long Uneven Recovery in India[*]

Mrinalini Jha[‡]   Rahul Lahoti[§]

September 1, 2022

Abstract

We investigate the impact of the Covid-19 pandemic on income levels, poverty, and inequality in both the immediate aftermath and during the long uneven recovery till December 2021 using high-frequency household survey data from India. We find that the average all-India household income dropped between 30 to 38 percent during the months of the nationwide lockdown of April and May 2020. The subsequent recovery remained incomplete and was unevenly spread over the population even twenty-one months after the start of the pandemic. Households on an average continued to make 16 to 19 percent lower cumulative income in the post-lockdown period, but have mostly recovered after the second wave in the second half of 2021. Poverty more than doubled during the lockdown and was 50 to 80 percent higher in the post-lockdown period in comparison to the pre-pandemic levels. In the post-second-wave phase, poverty was still slightly higher than in the pre-pandemic period, and any progress in poverty reduction that would have been achieved under normal circumstances over the two years was lost. Inequality too spiked during the lockdown, but returned back to the pre-pandemic levels. Using an event study model we find that the initial shock of the lockdown was more severe for the bottom of the income distribution, but the bottom also experienced a faster recovery. On the other hand, the top end of the distribution experienced smaller declines during the lockdown but they have been slow to recover. The bottom deciles in any period typically constituted households working in contact-intensive, informal, less secure occupations that were hit the hardest during the lockdown, but were quick to recover when the economy opened up. The upper end of the distribution constituted households working in less contact-intensive, formal, secure occupations that were shielded from the sudden shock but were slow to recover.

1   Introduction

Covid-19 pandemic has had a significant impact on economic activity worldwide on two accounts. One, on account of the health crisis itself, and two, as a fallout of the various containment measures imposed across the different economies (Narayan et al., 2022; Miguel and Mobarak, 2021; Egger et al., 2021). The distributional impact of the pandemic in developing countries has been estimated using growth projections (Sumner et al., 2020; Deaton, 2021; Decerf et al., 2021; Mahler et al., 2020), simulations (Alkire et al., 2021), nightlights (Beyer et al., 2021), models applied on data collected from high-frequency phone surveys (Narayan et al., 2022), or from purposive surveys (Kesar et al., 2021; Jaacks et al., 2021; Mahmud and Riley, 2021). However, all of the above methods have serious shortcomings in accurately estimating the impact of the pandemic on different sections of the population. Due to the highly infectious nature of the pandemic, collection of high-frequency, nationally-representative livelihoods and income data through household surveys has been difficult and thus rare, especially in developing countries. In addition, though the initial impact of the containment measures (lockdowns) is well understood, the subsequent nature of the recovery and its distributional impacts have not been explored enough.

In this paper we investigate the impact of the pandemic on the distribution of income, poverty, and inequality in India using high-frequency longitudinal data. In particular, we investigate the impact of the pandemic-led containment measures, and the nature of the subsequent recovery over almost two years[1] since the start of the pandemic. We examine who was impacted and how by analyzing the impact and recovery across various groupings, and tracing the changes in income over the period January 2018 to December 2021.

We estimate poverty and inequality during the pre-pandemic period (January 2019 to February 2020), the lockdown period[2] (March 2020 to May 2020), the post-lockdown period (June 2020 to March 2021), the second wave (April 2021 to June 2021), and the

---

[1]We cover twenty-two months from March 2020 to December 2021.

[2]In this paper, unless otherwise mentioned, lockdown refers to the first nationwide lockdown imposed on March 24th, 2020.

post-second wave period (July 2021 to December 2021) in India. We use the Consumer Pyramids Household Survey (CPHS) collected by the private agency Centre for Monitoring Indian Economy (CMIE). Using an event study framework, we also estimate the change in monthly per capita household income in each month for each income decile as compared to two baselines - one, compared to the pre-pandemic levels (February 2020) and two, compared to the counterfactual income had the pandemic not occurred. Our analysis controls for all time-invariant household characteristics. We also examine the occupational channel through which the distributional impact of the pandemic is operating. We undertake extensive heterogeneity analysis to determine how the drop and recovery in incomes vary by different socio-economic groups - caste identity, religion, human development index (HDI) of states, and percentage of migrant populations in states [3].

Our first set of findings show that there was a sharp drop in incomes during the lockdown, and incomes have not recovered fully leading to elevated poverty levels even twenty-two months after the start of the pandemic. Inequality increased during the lockdown but thereafter began to lower and has returned to the pre-pandemic levels in the post-second wave phase. Inequality as measured by the Gini index spiked from 0.44 (0.41) to 0.51 (0.46) during the lockdown period and returned to 0.44 (0.37) in the post-second wave period in the rural (urban) sector. An average individual in a rural household lost 30 percent of their cumulative income during the three months of lockdown as compared to the pre-pandemic period. The corresponding loss in cumulative incomes for an individual in an urban household was 37 percent. In the post-lockdown period an average individual's cumulative income in a rural (urban) household continued to remain 16 (19) percent lower than the pre-pandemic period. The second wave led to a

---

[3]The choice of these groupings comes from a characterization of households on the basis of their *pre-pandemic* features. We purposefully do not use any feature of the pandemic itself for doing heterogeneity analysis, e.g. severity of the spread of the pandemic, deaths due to the pandemic, strictness of containment measures, etc. This is out of scope of this paper primarily because of lack of good-quality, reliable data offering these categorizations. For example, infection rates vary across states not just because of the extent of spread of the disease but also due to the differential testing policies and infrastructure in the states. Death rates are unreliable because of varying level of under-reporting of deaths across various states. Strictness of containment measures is dependent both on spread and policy at the state level.

sharp drop in incomes for a month, after which they recovered. By end of 2021, incomes in rural areas had recovered to pre-pandemic levels but in urban areas were still 10 percent below February 2020 levels. The entire income distribution shifted leftwards. There was more than a twofold increase in poverty during the nationwide lockdown[4]. The percentage of individuals living in households that earn below the national minimum wage on a per capita basis increased from 33 (18) percent before the pandemic to 62 (56) percent during the lockdown in rural (urban) areas. The recovery is only partial even about two years since the lockdown was lifted. Even in the post-second wave period the poverty rate was 36 (24) percent in the rural (urban) areas.

Our second major finding is that the lower part of the distribution witnessed larger drops in their income in the lockdown period but experienced relatively quicker recovery. On the other hand, the upper end of the distribution witnessed smaller initial decline in income during the lockdown and were slow to recover back to pre-pandemic levels. The bottom twenty percent lost almost their entire income during the lockdown and bounced back rapidly afterwards. The top of the distribution experienced smaller initial shock during the lockdown (between 10 to 20 percent) but their recovery was lagged. The top decile in every month, especially in the urban areas, stagnated, remaining 14 percent below their pre-pandemic levels in December 2021. This pattern across the distribution can be explained by how different occupations were impacted by the lockdown and the subsequent economic downturn. Contact-intensive and less secure occupations like wage labourers were impacted severely in the lockdown. These occupations lost jobs due to the largely informal nature of their work and lack of any secure contract and had a sharp drop in incomes. When the economy opened they were able to recover their lost jobs and earnings. In any typical month, such workers are more populous in the lower end of the income distribution, and hence the lower part of the distribution witnessed the sharp dip and sharp recovery pattern. On the other hand, more formal occupations that are less contact-intensive and have some job security so were slightly protected from the impact of national lockdown. They experienced smaller drops in income in the

---

[4]Migration of individuals might have some impact on poverty estimates but we do not have data to account for that and believe that impact would be small as compared to the overall increase. The major impact might be of reduced remittances.

immediate aftermath of the pandemic but they also saw a slower recovery back. The slow recovery being potentially on account of the longer procedures involved in rehiring workers in such occupations, or the lag in recovery after a pay cut, unlike those in daily wage work, etc. Workers belonging to such formal occupation types typically belong to the upper end of the income distribution. We provide evidence to substantiate this theory.

The third major finding is the suggestive evidence that the containment measures (lockdown) had a far greater impact on economic activity than the self-imposed behavioral changes due to fear of the spread of the disease itself. The nationwide lockdown between March 2020 and May 2020 saw a more than 30 percent decline in incomes on average with the poor losing almost their entire income. In contrast, the drop in incomes during the peaks of the two waves[5] was of a much smaller magnitude and the recovery was quick as these periods were not accompanied by national lockdown.

All these results are robust to different assumptions and alternate specifications. Poverty increase is observed across different poverty lines and inequality changes are observed across different inequality measures. The pattern of changes in incomes across the various deciles is qualitatively similar across different specifications. The results remain similar with and without adjustments to monthly incomes for seasonality. Across different heterogeneous groupings we find that the disadvantaged groups were impacted more.

Our analysis has implications on both fiscal and welfare policies. We find that complete lockdowns have had a far more deleterious impact on the poor than the rich. Even though the poor, on average, experienced a quick partial recovery, the economic impact borne by them was not of a temporary nature. With low (often zero) savings and mostly informal sources of borrowing, even full recovery of monthly income does not necessarily translate into an overall full recovery back to the pre-pandemic levels. The sudden, overnight shock of the lockdown led people to liquidate their assets and incur heavy borrowing for daily sustenance, which in turn implied that they continue to suffer

---

[5]The first wave peaked in September 2020. The second wave which had a far more devastating impact in terms of human lives peaked in April-May 2021.

a prolonged effect of the pandemic (Nath et al., 2022). Consequently, there remains an urgent need for providing direct support to tackle food insecurity as well as to assist the poor to enable them to sustain themselves (Sinha, 2021; Drèze and Somanchi, 2021; Mishra and Rampal, 2020). Our findings also build a case for better funding and further expansion of both rural and urban job schemes in the country (Dhingra and Machin, 2020; Basole, 2021).

There have been several concerns raised about the CMIE-CPHS sample and data collection process (Dreze and Somanchi, 2021; Somanchi, 2021; Pais and Rawal, 2021; Sinha Roy and Van Der Weide, 2022). One of these concerns is that the CPHS systematically misses sampling the very poor (Somanchi, 2021), and its earnings distribution starts at higher income levels as compared to other nationally-representative surveys (Jha and Basole, 2022). We argue that even in the presence of these concerns, their most likely implication would be that our results are conservative estimates of the extent of poverty and inequality changes.

Our results are similar to those obtained from other poverty estimations that find a substantial increase in poverty across the developing world (Sumner et al., 2020; Narayan et al., 2022; Egger et al., 2021; Bottan et al., 2020) and specifically in India (Center, 2022; Basole et al., 2021). Several smaller surveys in India also find large the informal sector was impacted severely during the pandemic (Kesar et al., 2021; Ceballos et al., 2020), and this too is indicative of a subsequent rise in poverty.

Gupta et al. (2021) also use CPHS data to study inequality and poverty in India during the pandemic. Their findings are substantially different from ours. They classify households into quartiles based on 2015-19 incomes and then these static (fixed) quartiles are tracked over the pandemic. So the change in incomes of the households are tracked over time. We on other hand, assign households to deciles base on each month's income. So households in our analysis could be assigned to different deciles based on their month's income. We track the decile incomes over time. Gupta et al. (2021) claim that inequality *declined* during the pandemic because the households who were deemed rich prior to the pandemic were impacted more than their poorer counterparts. This interpretation is problematic. Income inequality may be broadly defined as how

unevenly incomes are distributed across the population, and is usually measured using some measures of inequality like Gini or Theil index or ratios of income of the various quantiles of the distribution. According to all these measures inequality spiked during the lockdown and has now returned to pre-pandemic levels, *not* substantially declined. Their finding of progressive change, as the authors argue, might have occurred due to upward social mobility during the pandemic. But since mobility and inequality are two different concepts, it is incorrect to interpret it as a fall in inequality.

Tracking households allows one to study mobility over time and derive richer results, but sample attrition needs to be handled with care. This is particularly the case with CPHS data during the lockdown and the period of the pandemic. CPHS interviews moved from in-person to on-phone in the beginning of the lockdown and the response rate of the subset of households that were contacted fell to roughly 60 percent, with the responding households constituting roughly 35 percent of the full sample during the lockdown. The bias resulting from this might impact the results which has not been systematically investigated by the authors [6].

Our work contributes to multiple strands of literature. First we contribute to the literature on the impact of the pandemic on incomes, poverty, and inequality in developing countries (Narayan et al., 2022; Sumner et al., 2020; Reddy, 2021; Rönkkö et al., 2022). Ours is among the few studies to use nationally-representative household income data to examine the impact of pandemic. By investigating the distributional impact of the long and uneven recovery we stretch the boundaries of the existing work, which focus on the initial lockdown phase but not on the distributional impact during the period of post-lockdown recovery. We also investigate the channel through which the distributional impact operates, that of occupation. Further, we focus on India which has the largest number of poor in a single country across the world, combined with its large population, and hence has critical implications on global poverty and inequality.

Second, we contribute to the literature on measuring poverty and inequality in India (Sahasranaman and Kumar, 2020; Edochie et al., 2022; Sinha Roy and Van Der Weide,

---

[6]It is partly for this reason that we classify households into deciles based on each month's income (dynamically) whereas Gupta et al. (2021) define quantiles based on the average 2015-19 incomes and then track those households.

2022; Bhalla et al., 2022; Gupta et al., 2021). Since the latest published official household survey dates back to 2011-12, there is considerable uncertainty about recent poverty trends in the country. Our work, even though based on a new and different dataset, provides insights into the levels of poverty and inequality in India.[7]

Third, our results provide some insights which contribute to the debate on the right kind of policies that should be implemented during a pandemic. There has been a debate on how to get the right balance between policies that reduce health risks of the disease and those that reduce the economic impact of the containment measures (Schotte et al., 2021; Ray and Subramanian, 2020; Robalino, 2020). By providing estimates of the economic impact of the national lockdown and containment measures during the second wave[8], our work adds to this literature too.

The following section elaborates upon the data used in the study with a detailed discussion of the methodologies adopted for the analysis. Section 3 describes the income trends and cumulative losses over the entire income distribution. Section 4 discusses the implications on inequality and poverty in the pre-pandemic, lockdown and post-lockdown period, as well as in a counterfactual scenario of no-pandemic. Section 5 elaborates on the findings from the event study analysis, focusing on both - the impact across income distribution, as well as that for different occupation categories. Section 6 gives the event study results from the different heterogeneity groups. Section 7 offers a discussion on the CMIE-CPHS data, briefly describing the recent debate on the dataset and what it implies for our findings. Section 8 concludes with a brief summary of the results.

2 Data and Methodology

2.1 Data Description

We use the high-frequency CMIE-CPHS survey data from January 2018 to December 2021. The survey is a panel wherein each household is interviewed three times a year,

---

[7]Poverty and inequality levels in NSS or IHDS data are not directly comparable to CPHS data since the sampling and survey methodology are substantially different.

[8]Only partial lockdowns were imposed during the second wave.

in three "waves". The survey in its current form has been running since 2014 and has around 200,000 households (900,000 individuals) across the country. The sample of households was drawn using a multi-stage stratified survey design, with villages and towns of the Census 2011 being the primary sampling units (PSUs), and the households belonging to these PSUs being the ultimate sampling units (USUs).[9]

The survey response rate was high prior to the pandemic but dropped significantly during the lockdown and has only partly recovered. The response rate of the survey was 84 percent in 2019. This dropped to a low of 44 percent during the wave that included the lockdown months (May'20 to August'20). The response rate has fluctuated between 65 to 75 percent since then. The survey was conducted only on the phone between end-March 2020 and mid-June 2020. Phone surveys could lead to a downward bias in the reported incomes due to survey fatigue. Part of the large decline in incomes we find during the lockdown might be due to this bias. **??** find in an experiment in urban Ethiopia that respondents phone surveys led to lower consumption reporting as compared to in-person surveys.

CPHS provides household and individual level data under four groups - Income, Consumption, People of India, and Aspirational India, starting 2014. In each visit, income information at the household as well as the individual level is asked for the previous four months. So in total, CPHS provides income information for every month and for every individual. The variable used for the income analysis in this study is per-capita household income. This comprises all kinds of earnings, including wages, business income[10], rent, private transfers, income from self-production, overtime, bonus, pension, dividend, interest, deposit provident fund, public provident fund, and insurance. It sums up the incomes earned by every member of the household along with those which are attributed to the house itself and not necessarily individuals in the household. All incomes reported in the paper are in constant January 2020 prices.[11]

---

[9]More details on the sampling strategy can be found here - https://consumerpyramidsdx.cmie.com/kommon/bin/sr.php?kall=wkb

[10]CPHS does not include losses in the business owner's income. It is treated as part of the business accounts. Consequently, CPHS does not report negative incomes.

[11]The conversion is done using the consumer price index released by the Reserve Bank of India. We use the General Index for each state, separately for the rural and urban sectors. The general index subsumes all groups, e.g., food and beverage, clothing and footwear, housing, etc.

Occupation information for all members of the household is collected once every four months.[12] CPHS also classifies households based on the occupation composition of the members of the household into twenty distinct categories. We aggregate these categories into seven to eight groupings based on their contact intensiveness and vulnerability to sudden shocks. This is done separately for the rural and urban areas. More details on the categories are in Table A2 in the appendix.

2.2 Seasonality Adjustment

In our analysis, the main results for income are adjusted for seasonality so as to facilitate month-over-month comparisons. Rural incomes vary based on harvest seasons, whereas urban areas have limited seasonality associated with festive seasons. Seasonality adjustment factors for each month are estimated by calculating the average deviation in monthly incomes from the trend-line experienced in the 2017-2019 period. We estimate incomes for each individual month by calculating a moving average of the monthly incomes of the surrounding ten months (five months prior to the month under consideration; five months post). The observed income in the month is then divided by the estimated income to get a ratio of the deviation from the trend-line. This is done for every month's data between June 2017 and September 2019. The month-specific seasonality adjustment factor is then derived by taking an average of all the ratios for a given month over the two-year period. This adjustment is done separately for rural and urban sectors. We then apply this seasonality factor to each month's income in 2020 to get the seasonally adjusted incomes. For example, rural income for January 2019 is estimated by taking an average of monthly incomes five months prior to that month (August 2018 to December 2018), and five months after that month (February 2019 to June 2019). This is then divided by observed income in January 2019 to obtain a ratio of the estimated to observed incomes. Similarly, a corresponding ratio for January 2018 is estimated. January 2019 and January 2018 ratios are then averaged to get a

seasonality adjustment factor for the month of January. This factor is then applied to January 2020 and January 2021 incomes. As expected, incomes are found to be more seasonal in the rural areas as compared to those in the urban areas because of lump-sum incomes obtained by farmers when they sell their harvest. Typically, rural incomes for the months of April and October are higher.[13]

2.3   Cumulative Analysis

There are expected to be sharp variations in employment and income during the pandemic either due to the pandemic-induced containment measures or due to the infection rates. This makes it difficult to understand the impact of the pandemic on longer-term welfare outcomes by just looking at the monthly data. To tackle this frequent fluctuation, we aggregate months into different phases and study the average impact on welfare measures like poverty and inequality during these phases. We divide the time period into five phases - based on the intensity of the containment measures and the spread of the virus. Covid-19 infection rates and changes in mobility as measured by Google Mobility data for the different phases are shown in Figure 1. The first phase is the pre-pandemic phase from January 2019 to February 2020 which forms our baseline for comparison of the impact. The second phase is the lockdown period from March 2020 to May 2020 when there was a nationwide lockdown. The third phase is the post-lockdown period before the onset of the second wave from June 2020 to March 2021. This period saw the first wave of infections that peaked in September, but economic activity as seen by mobility rates recovered substantially in comparison to the lockdown period. The fourth phase is the second wave from April 2021 to the end of June 2021. This phase witnessed the deadly second wave in which millions across the country lost their lives due to the pandemic. There was no national lockdown imposed during this period but several local and state governments imposed different containment measures including partial lockdowns. The last phase is the post-second wave period from July 2021 to December 2021. The pandemic eased during this period and mobility slowly returned

---

[13]Seasonality adjustments are not done at the occupation level so there may still remain some fluctuations in incomes for some particular occupations due to the seasonality of incomes.

to its pre-pandemic levels.

We investigate the changes in household income distribution, poverty rates and inequality during the five phases to understand the welfare impacts of the pandemic and the subsequent recovery.

2.4 Event Study

In order to analyse the changes in household incomes during the pandemic period we perform an event study analysis. The announcement of the national lockdown in March 2020 is the event of interest. The event study regression helps us estimate the change in incomes relative to different benchmarks. The first model compares monthly income to pre-pandemic income (February 2020), and the second model compares each month's actual income to the predicted income in that month, i.e., a counterfactual in the scenario where there was no pandemic.

The first event study model is the following:

$$(y_{it} - \bar{y}_\delta)/\bar{y}_\delta = \sum_{\substack{\tau=-26 \\ \tau \neq -1}}^{\tau=21} \beta_\tau .1[\tau = t - e] + \alpha_i + \epsilon_{it} \tag{1}$$

wherein,

y_{it} = seasonally adjusted per capita income in real terms for household i in month t for group j.

δ = pre-pandemic period (month of February 2020)

$\bar{y}_\delta$ = seasonally adjusted average per capita income in real terms for households in February 2020.

τ = indexed event time (time relative to the month of lockdown – March 2020)

e = base month (March 2020)

α_i = household fixed effects

ϵ_{it} = error term (clustered at the household level)

Equation 1 is used to get the proportionate change in seasonally adjusted real per capita household incomes in month t relative to average group income in February 2020,

for households belonging to different heterogeneous groups[14]. Our analysis starts from January 2018 (26 months before the lockdown τ=-26) to December 2021 (21 months after the lockdown τ=21). As is the norm in the event study analysis, we omit the month before the event - February 2020 (τ=-1). The coefficient β_τ measures the proportionate change in income of household i in the month τ as compared to the average income of households in February 2020. Household fixed effects control for any time-invariant characteristics of the household like social group identity, location etc.

The regression is run separately for rural and urban areas. To study the differential impact of the pandemic across the income distribution, we order the households in rural and urban areas separately by per capita household income of each month. Households in each month are then divided into ten bins - deciles[15]. Each decile is treated as a different group. The regression is run for households belonging to each decile separately to estimate the change in income of each decile. As the households constituting the deciles might change over time, our results should be interpreted as the change in the average income of the decile and not of particular households, since we are not tracking households.

To understand the patterns of change in incomes better, household occupation categories constitute another grouping variable. We run the regression separately for each occupation group to understand how contact-intensive occupations, occupations primarily in informal sectors and formal sectors fared in the pandemic. We do not have a control group in this model - counterfactual - to what would have happened in the absence of the pandemic and containment measure as it was a nationwide event, so we do not claim any causality in our analysis. The second model addresses this concern partly by constructing a counterfactual trend of income based on the past. Also, we cannot use our data to separate the impact of the containment measures (lockdown) and the impact of the change in behavior due to fear of infection.

In the second model, we compare incomes in each month with predicted incomes in a

---

[14]Groups can refer to all-India, region(rural/urban), income deciles, caste categories, religion, state groupings using HDI, state groupings using migrant population, etc.

[15]These are dynamic deciles as households belonging to them might vary across months based on their income in that month.

scenario where pandemic had not occurred. Income predictions for March 2020 onwards are calculated on income patterns between January 2018 and February 2020 using the equation below:

$$y_{it} = \beta_1 * month + \beta_2 * year + \omega_{it} \tag{2}$$

We estimate the coefficients of the above model based on observed income data from January 2018 to February 2020 and then use those coefficients to predict per capita income levels $\hat{y}_{it}$ for every household i in every month t. This is again done for the different groups to which households may belong. $\hat{y}_{it}$ is obtained for each group separately. We then estimate a modified version of equation 1 where the change in incomes is measured in comparison to the mean of the predicted income for the group ($\hat{y}_t$) instead of mean income levels in February 2020 ($\bar{y}_\delta$). The modified equation is below:

$$(y_{it} - \hat{y}_t)/\hat{y}_t = \sum_{\substack{\tau=-26 \\ \tau \neq -1}}^{\tau=21} \beta_\tau . 1[\tau = t - e] + \alpha_i + \epsilon_{it} \tag{3}$$

where: $\hat{y}_t$ = average predicted per capita income in real terms for households for the month t.

The procedure to calculate predicted income uses incomes from the last two years to predict the trend and then estimate the predicted income for each month. If we reduce or increase the length of time in the past used to predict incomes it may change the predicted values. Additionally, if we decide to give more weightage to the recent past and less to distant past to predict future incomes, that too may impact the predicted values. Our estimation in equation 1 compares income to the most recent past before the pandemic and in equation 2 we compare incomes to predictions based on long-term income. This provides two different perspectives on the change in incomes. Both are not perfect counterfactuals, but provide a range of counterfactual incomes against which we can compare the pandemic-era incomes.

It is also likely that the impact of the pandemic varies by social groupings and geo-

graphical location of the household. Impact might be different by social groups (caste and religion) because groups tend to be concentrated in particular types of occupations that are differentially impacted, or access to resources and networks may vary by group identities. Pre-pandemic characteristics of location (states classified according to cross-state migration status and pre-pandemic human development index) of the household may lead to heterogeneous impact because of varying levels of infrastructure and governance. Based on the migrant population we categorized states into two groups - those with low percentage of migrants, and those with high percentage.[16] The second categorization of states is according to their Human Development Index (HDI) levels in 2019. Three categories of states are considered - low HDI, medium HDI, and high HDI. [17]

We do not claim causality in the heterogeneity analysis due to endogeneity and other aspects that may also contribute to the differential impact, instead we use these heterogeneous categories to illustrate the correlations. We conduct the heterogeneity analysis for poverty and the event study analysis.

3   Descriptives

3.1   Trend Analysis

Incomes fell sharply for everyone during the pandemic-induced lockdown, the immediate drop being more drastic for the urban sector. The average monthly per capita household income of India was Rs. 5,404 in February 2020. Compared to this immediate pre-pandemic level, the average monthly incomes declined in real terms to Rs. 3,574 in April, a drop of 34 percent (Figure 2). Since the pandemic and the containment measures had

---

[16]Low migrant states are Jammu & Kashmir, Bihar, Meghalaya, Nagaland, Uttar Pradesh, Jharkhand, Rajasthan, Assam, Madhya Pradesh, Chhattisgarh, Tripura, Odisha, and West Bengal. High migrant states are Himachal Pradesh, Sikkim, Haryana, Karnataka, NCT of Delhi, Tamil Nadu, Uttarakhand, Andhra Pradesh, Gujarat, Arunachal Pradesh, Punjab, Maharashtra, Kerala, Pondicherry, and Goa.

[17]Low HDI states are Bihar, Chhattisgarh, Jharkhand, Tripura, West Bengal, Madhya, Pradesh, Odisha, Assam, Uttar Pradesh, Rajasthan, Andhra Pradesh, and Meghalaya. Medium HDI states are Gujarat, Maharashtra, Jammu & Kashmir, Karnataka, Arunachal Pradesh, Telangana, Nagaland, and Uttarakhand. High HDI states are Sikkim, Delhi, Goa, Haryana, Himachal Pradesh, Kerala, Puducherry, Punjab, and Tamil Nadu.

a greater impact on urban economic activities, urban sectors suffered a sharper drop in incomes as compared to the rural areas (Figure 2). Income for a family of four in urban areas on average dropped by 47 percent (Rs. 13,400) between February 2020 and April 2020, while in rural areas the corresponding drop was 24 percent (Rs. 4,300).

As expected, immediately after the lifting of lockdown restrictions, incomes started recovering. A significant portion of the decline had recovered to the pre-pandemic levels by October 2020. All-India incomes increased steadily till January 2021 and after a minor dip, were above Feburary 2020 levels in April 2020. Incomes again dropped significantly in May 2021 which coincides with the peak of the second wave of the pandemic in the country. The all-India per capita real household income in May 2021 was 14 percent lower than the pre-pandemic level (February 2020). The average rural (urban) incomes in May 2021 were 12 (16) percent below the pre-pandemic level. Incomes recovered rapidly after the second wave and by December 2021 were close to or above the pre-pandemic levels.

An important caveat here is that these incomes have not been adjusted for seasonality and hence may include seasonal fluctuations in income due to harvest, festival season, etc. Incomes, particularly rural incomes, tend to be higher in the harvest months. Seasonally adjusted incomes give a more accurate understanding of the impact and the recovery, and so we use seasonally adjusted numbers for the remaining of our analysis. After adjusting for seasonality, the qualitative pattern of the sharp drop in incomes in the lockdown followed by recovery remains the same (Figure A3). The gap in losses between the rural and urban areas narrows significantly after the seasonality adjustment as the relative drop in rural income increases after the adjustment. The seasonally adjusted drop in incomes in the rural areas is 39 percent between February 2020 and April 2020 as compared to the 24 percent drop in the unadjusted incomes. The corresponding numbers for the urban areas are 51 percent with the adjustment and 47 percent without the adjustment for the same period (Figure A3). Further, while the seasonally adjusted incomes in December 2021 were back to the pre-pandemic levels for the rural areas, the levels continued to remain around 4 percent lower than the pre-pandemic levels in the urban areas (Figure A3).

16

3.2 Cumulative Analysis

To understand the aggregate impact of the pandemic on distribution, poverty and inequality we estimate them for the five aggregate periods outlined in section 2.3. Figure 3 plots the per capita household income distributions for the five different periods in rural and urban areas. The distribution moved significantly to the left during the lockdown phase with the mean per capita household incomes declining by 30 percent in rural areas and 37 percent in urban areas. Even in the post-lockdown phase, the distribution has not fully recovered to its pre-pandemic state. The average per capita household incomes in the post-lockdown phase were 16 percent lower in the rural areas and 19 percent lower in the urban areas, as compared to pre-pandemic levels. The second wave saw a deterioration in conditions for many and the distribution shifted to the left, but incomes were higher than the lockdown phase. The post-second wave period saw a significant recovery. The distribution in rural areas moved right of the pre-pandemic distribution for large portions of the distribution. The urban distribution, especially the top of the distribution, did not experience as strong a recovery and was to the left of the pre-pandemic distribution for most parts. Even when we compare some select pre- and post-pandemic months, its clear that the distribution has shifted to the left and has not fully recovered (Figure A4).

Plotting the growth incidence curves we find that the impact was uneven across the distribution in the different phases (Figure 4). The lockdown phase, and to some extent the second wave period, saw lower percentiles experiencing more declines in incomes than the higher percentiles. The lockdown period saw lower average declines in income as one climbed up the income ladder as compared to the pre-pandemic period (except for the top 1 percent in rural areas that experienced a minor increase in income). Almost all income percentiles in urban areas experienced larger drops in income on average during the lockdown period as compared to their corresponding rural percentiles.

However, the impact in the two recovery phases (post-lockdown and post-second wave) is similar across large parts of the distribution (Figure 4). The post-lockdown phase witnessed a similar average drop of between 15 to 20 percent across the income

distribution in both the rural and urban areas (except for the households in the top and bottom 5 percent of the distribution). In the post-second wave period rural areas have recovered better than urban areas across the distribution (except for the bottom 10 percent). The recovery is similar for most of the middle of the distribution. The top 20 percent in urban areas seem to farthest from complete recovery in the post-second wave period than other percentiles.

4   Poverty and Inequality

4.1   Poverty

Poverty increased substantially during the lockdown and has recovered only partly in the recovery phases. Poverty increased substantially during the lockdown, then recovered partly in the post-lockdown phase but experienced a deterioration during the second wave. The post-second wave period saw an improvement in the situation but on average poverty still was slightly above the pre-covid levels (Table 1).

The proportion of people living in households earning less than the national minimum wage[18] almost doubled in the rural areas and more than tripled in the urban areas during the lockdown. Poverty in the post-lockdown phase was 1.3 (1.6) times higher in the rural (urban) areas as compared to the pre-pandemic period. Poverty worsened during the second wave, but saw an improvement in the post-second wave period in both rural and urban areas. In the post-second wave period on average poverty was slightly above the pre-covid levels, particularly in rural areas.

In the absence of pandemic poverty would have declined with economic growth, as has been the case in most pre-pandemic years. But any potential progress in poverty reduction for these two years was whipped out by the pandemic and during this phase the situation was worse. This would have led to dip in savings, if any, and asset sales

---

[18]We use the definition of the national minimum wage proposed by the Anoop Satpathy committee. The recommendation was Rs. 375 per day (Rs. 104 per capita per day) for rural areas and Rs. 430 (Rs. 119 per capita per day) for urban areas as of July 2018. This works out to Rs. 2,900 per capita per month and Rs. 3,344 per capita per month respectively after adjusting for inflation in January 2020 terms. This is also consistent with Indian labour Commission (ILC) norms and the Supreme Court guidelines.

impacting the long-term productivity and welfare of households.

A similar pattern exists even by different definitions of poverty lines, though the extent varies (Table 1). Even when we compare select months, poverty is still higher than the pre-pandemic months (Table **??**).

We find that poverty saw substantial increase across various groupings by caste, religion and state groups, but the extent varied. The intermediate caste saw higher increases in poverty during the lockdown phase and recovery was worse than other caste (Table A4). The increase in poverty was highest for the Other religion category (Table A5). States with High Human Development Index saw significantly larger increase in poverty (Table A6). The proportionate increase in poverty was far higher in all periods in the states that fall in the category of in-migration states as compared to the out-migration states (Table A7).

4.2   Inequality

We find that inequality increased drastically during the lockdown phase but has largely returned to the pre-pandemic levels after the lockdown. In rural areas and as per some inequality measures (General Entrophy measures) and in urban areas inequality levels in the post-second wave period are below that of pre-covid period. We estimate different inequality measures - Gini, General Entropy Measures and ratio of 90 to 10 percent - and the results are consistent across these measures (Table 2). The increase in poverty accompanied by no change in inequality in the post-lockdown period indicates that there was a shift in entire distribution towards lower incomes as shown in 3. The decline in inequality in the post-second wave period might indicate the slow recovery for the top end of the distribution. Examining inequality for select months also indicates similar qualitative findings of an increase in inequality followed by a decline below pre-covid levels (Table A8). Household surveys, including CPHS, do not capture the top end of the distribution and hence usually understate the level of inequality and the trends in inequality might also be impacted if the top end of the distribution performs differently than the other parts of the distribution.

5 Event Study

To understand the impact of the national lockdown and the pandemic on incomes we estimate equation 1 for the rural and urban areas separately. The pandemic and the subsequent lockdown led to a 37 (48) percent drop in the seasonally-adjusted per capita real household income in April 2020 relative to February 2020 in rural (urban) India, controlling for all time invariant household characteristics. Income levels recovered rapidly as the lockdown was relaxed, and were 16 percent (18 percent) below the pre-pandemic levels in August 2020 in the rural (urban) areas. This was followed by a slow recovery. May 2021 witnessed a sharp drop in incomes in both rural and urban areas as this was the peak of the deadly second wave of the pandemic. In May 2021, incomes were 23 (26) percent lower than February 2020 in the rural (urban) areas. But the recovery from this drop was fast - within 1-2 months incomes were back to levels observed before the second wave. There was no national lockdown during the second wave, only state and local containment measures. Even though we cannot separate out impact of lockdown from self-imposed preventative measures, the lower drop and sharper recovery from the second wave as compared to the first national lockdown indicates that lockdown might have a larger economic impact than the self-imposed behavior changes due to the threat of infection. By December 2021 average rural incomes were back to the pre-pandemic levels. The urban recovery though was far from complete, with average incomes continuing to be 10 percent below the pre-pandemic level (Figure 5).

5.1 Impact across the Income Distribution

We measure the differential impact on different segments of the income distribution by tracing the change in average incomes for each decile in the event study framework for every month vis-a-via February 2020. Deciles are created using per capita household income for each month, and this analysis helps us track how deciles performed over time [19].

---

[19]Households are assigned to deciles each month based on their per-capita household income. So households might be in Decile 1 in one month and be classified to be in Decile 5 next month if their relative income increases. Our analysis helps track how decile incomes performed during the pandemic,

The pandemic led to a monotonic drop in incomes in April 2020 with a sharper fall in incomes for the bottom two deciles followed by the upper deciles, with the least fall experienced by the top decile. The bottom 20 percent of urban households lost almost their entire income in April 2020 due to the pandemic, while the top 20 percent in April 2020 lost between 20 and 30 percent of their incomes. For the rural households too there was a more than 90 percent drop in incomes for the bottom two deciles, and between 15 to 30 percent for the top two deciles in April 2020.

The bottom deciles in both rural and urban areas recovered a large portion of the drop experienced during the lockdown by August 2020. The recovery in incomes in both rural and urban areas was the sharpest for the lower deciles starting June 2020. The top deciles saw the smallest drop in incomes during the lockdown, but their income levels did not recover substantially post-lockdown, and till May 2021 remained largely stagnant, sometimes even lower than the initial drop experienced in April 2020. During the second wave in May 2021, almost all deciles experienced a sharp drop - with the drop being higher in urban areas and for lower deciles. By August 2021 income levels for all deciles, except the top, [20] in both rural and urban areas had recovered back to their pre-pandemic levels.[21] (Figure 6).

Across most of the deciles in the urban and rural areas, especially in the year prior to the pandemic, there are no pre-trends, except for the bottom two deciles in rural areas. The change in incomes in the pre-pandemic period are not significantly different across deciles in the urban and rural areas, except for the poorest decile in the rural areas (Figure 6). The change in income level for the bottom decile in the rural sector appears to be highly volatile and has a significant downward pre-trend. The bottom decile had a mean monthly income of Rs. 397 in January 2018. It remained roughly between Rs. 300 and Rs. 500 for every month till the end of 2019. Due to the acutely low levels of income for the bottom decile, even small absolute changes resulted in a large percentage change, which is visible in Figure 6(a). There is also likely to be a larger measurement

but we are not tracking a static set of households.

[20]The top decile in each month in the urban areas did not show any recovery. These deciles continued to remain 15-20 percent below the pre-pandemic levels.

[21]We report the change in income levels for the rural and urban sectors along with their levels of significance in Tables A9 and A10 in the Appendix.

error when measuring incomes at the bottom.

In addition to estimating the change in income as compared to the pre-pandemic income levels (February 2020 income), we also estimate equation 3 wherein we compare incomes with the predicted incomes in a counterfactual scenario where the pandemic has not occurred. This helps us check robustness of our findings against an alternative counterfactual. Figure 7 plots the percentage change in seasonally adjusted per capita income vis-a-via the predicted income[22]. If the decile income trend intersects with zero line, it means that decile income is the same as the predicted income for that month. If it's below this level then decile income is less than the predicted income and vice-versa. The pattern of decline in income during the lockdown and the immediate recovery is similar to the trends we get when looking at the changes in income compared to February 2020.

The bottom deciles in April and May 2020 experienced larger declines as compared to upper deciles in these months, in both rural and urban areas. But in later periods rural bottom deciles are farthest away from predicted incomes almost throughout the recovery. So they appear to have the worse recovery, but this needs to be read with caution. Rural bottom deciles, and the rural sector as a whole, experienced large drop in incomes pre-pandemic (starting from September 2019)[23]. So they were well below the predicted income (based on the trend line drawn using two year data) before the pandemic hit. Even though they recovered from the lockdown, they were still far away from the predicted income. Rural bottom decile were 45 percent below predicted income in Feburary 2019 and had recovered to be 25 percent below predicted income in December 2021. Rural top decile income in Februrary 2020 was same as predicted income but they were about 15 percent below predicted income in December 2021.

---

[22]The percentage change in incomes along with their levels of significance are presented in Tables A11 and A12

[23]This large drop pre-pandemic for the lower part of the distribution could be partly due to poor economic growth during 2019. GDP growth in 2011-12 prices was 3.1 percent in the last quarter of 2019, lowest in more than a decade.

5.2 Impact by Occupation Categories

The large drops during the lockdown followed by rapid recovery for households in the lower part of the income distribution and smaller drops along with slower recovery for households in the upper end of the income distribution could be explained by the differential impact of the pandemic on the different occupation categories. One hypothesis is that contact-intensive occupations like daily wage work or low-wage service sector jobs were impacted severely during the lockdown and recovered relatively quickly as the economy opened up. These are also jobs where there are no contracts so firing is easier and employers can rehire easily too. Households whose members tend to be daily wage workers constitute the lower deciles. As a result, the lower deciles witnessed a sharp drop and a speedy (partial) recovery.

Jobs that could be done remotely - formal sector jobs like white-collar professionals - were impacted minimally during the lockdown. These are also jobs that have relatively longer contracts so firing can take time and hence there is some short-term protection. Given the uncertainty surrounding the early part of the pandemic, employers might have been reluctant to fire or lower the wages of such workers immediately. As a result, this group experienced smaller immediate drops and a delayed impact. However, the job or wage losses suffered in these white-collar professions tend to be more permanent as employers are slow to re-hire or increase wages given the uncertainty in economic recovery and pandemic waves. Households whose members are in white-collar professional jobs also tend to earn more and belong to the upper end of the income distribution. Accordingly, the top of the distribution saw a much muted immediate drop, a delayed impact, but slower recovery.

This relationship between occupation categories, the differential impact of the pandemic on the different kinds of occupations, and the association of occupations with household income deciles could help explain the patterns we observe in our decile event study analysis.

We provide evidence to test this hypothesis by first examining the composition of each income quintile by occupation category of households. Next, we estimate the

changes in income for households belonging to each occupation category in the event study framework by estimating Equation 1 for each occupation category separately[24]. We have aggregated the occupation categories, to the extent possible, into categories that are more contact-intensive, informal, and less secure, and other categories that are less contact-intensive, formal, and with some protections from sudden changes in the contract. The split into categories is not perfect as occupations have multiple characteristics that do not always fit into this characterization.

In the rural areas, wage labourer's and agricultural labourer's jobs are more contact-intensive and more vulnerable to sudden shocks like the lockdown due to the daily nature of the contract. Entrepreneurs, mostly non-agriculture self-employed without any employees, even though they do not have a contract, have businesses that are more contact-intensive and less secure. All these three categories are more likely to belong to the bottom quintiles in the rural distribution (Table 3). For example, wage labourers constitute 19 percent of the population but are 30 percent of the bottom quintile. Agricultural labourers and entrepreneurs are more likely to be present in quintile 2 to 4 as compared to being in the top quintile. These groups experienced larger declines during the lockdown (85, 67, and 58 percent decline in April 2020 for wage, agricultural labour, and entrepreneurs, respectively) as compared to other groups. They recovered quickly, and by August 2020 were only 4 to 6 percent below their February 2020 levels (Table 4). By December 2021, income levels for these three categories of workers were among the closest to pre-pandemic levels.

In the rural areas the formal job category is mostly concentrated in the top two quintiles (Table 3). Formal jobs are 22 percent of the top quintile whereas they constitute only 13 percent of the population. This group experienced substantially smaller declines during the pandemic as compared to the wage labourers (40 percent vs. 85 percent in April 2020), but in August 2020 and January 2021 were further away from full recovery than wage laboureres. In December 2021, income levels for formal sector workers were 8 percent below the pre-pandemic level (Table 4). Farmers (big and small) are not easily

---

[24]The occupation categorization used is the categorization reported in each wave of the survey for the household and so might vary across waves for the same household.

classified into these categories as agriculture was exempted from the lockdown and they have no job contracts. They experienced smaller declines during the lockdown and had a volatile recovery.

In the urban areas, wage labour, agriculture labour, non-technical worker, and entrepreneurs (self employed) categories are more contact-intensive and vulnerable in terms of job contracts. These groups are more likely to be in the bottom quintiles (Table 5). For example, wage labourers are 15 percent of the overall population but 28 percent of the bottom quintile. All the three groups experienced sharper declines in April 2020 followed by rapid recovery, as compared to the other groups (Table 6). For example, wage labourers' income declined by 75 percent in April 2020, recovered rapidly to be only 17 percent below February 2020 levels in August 2020, and was only 6 percent below February 2020 levels in December 2021.

On the other hand, formal white collar workers in urban areas are less contact-intensive, and are secure in the short term in terms of job contract. They are also more likely to belong to the top quintile of the urban distribution (Table 5). These occupation groups experienced smaller declines in April 2020 and slower recovery in the next period as compared to the other occupations. Incomes of white collar workers dropped by 26 percent in April 2020, and recovered to below 19 percent in August 2020 after the lockdown. Even in December 2021 they were 17 percent below February 2020 levels (Table 6).

6 Heterogeneity

We now present results of the impact of the pandemic by social groupings and geographical location of the household. We estimate Equation 1 separately for each of the categories in these groupings.

6.1 Caste

The pandemic caused the sharpest drop in seasonally-adjusted monthly per capita incomes of Scheduled Caste (SC) households (Figure 8). They suffered a drop of 55 percent

in April 2020 as compared to February 2020. The income fall was between 40 and 50 percent for Other Backward Classes (OBC) and Scheduled Tribes (ST) households. ST experienced most rapid recovery and were close to the pre-pandemic levels by the end of 2020. SC and OBC also experienced substantive recovery from the decline during the lockdown. General Category (GC) experienced the least fall in incomes during the lockdown. Their incomes fell by less than 30 percent, but they also saw a slow recovery and their incomes continued to remain 10 percent below the pre-pandemic levels in December 2021. This pattern across caste categories might be because of occupational segregation by caste groups. SC and ST are more likely to be in low-end, contact-intensive occupations that recovered after the lockdown, whereas GC are more likely to be in the formal sector or the high-end occupations that recovered slowly. This pattern exists in both rural and urban areas (Figures A5 and A6).

6.2 Religious Groups

The pandemic led to the highest drop in incomes of Muslim households with more than 50 percent drop in their incomes in April 2020 as compared to February 2020. The drop was around 40 percent for Hindus [25]. Incomes recovered to about 5 percent below the pre-pandemic levels for Hindus and 10 percent below the pre-pandemic levels for Muslims by December 2021 (Figure 9). This pattern exists in both rural and urban areas (Figures A7 and A8).

6.3 HDI Levels

On categorization of states by Human Development Index (HDI), we find the drop in incomes in April 2020 to be similar for all categories - around 40 percent. The recovery was the quickest for the low HDI states. These states made a full recovery before the coming of the second wave. Recovery was not complete for either the medium HDI states or the high HDI states, the pace of recovery being the slowest for the high HDI

---

[25]We categorized households under three religious groups - Hindus, Muslims, and Others. Others category constitutes only 4 percent of the population. We show the graphs only for the two major religion groups - Hindus and Muslim.

states (Figure 10). By December 2021, the averge income in the high HDI states was around 20 percent lower than the pre-pandemic levels. A similar pattern exists in both rural and urban areas (Figures A9 and A10).

6.4 Migrant Population

The two grouping of states by the magnitude of migrant population suffered a similar drop in incomes in April 2020 - around 40 percent lower than February levels. However the recovery was differential. The low-migration states saw a quicker recovery and in fact made a full recovery back to the pre-pandemic levels before the second wave again caused a drop in incomes. In contrast, the high-migration states saw a slower recovery, remaining 10 percent below the pre-pandemic level in December 2021 (Figure 11). A similar pattern exists in both rural and urban areas (Figures A11 and A12).

6.5 Seasonality Adjustments

Seasonality adjustment might introduce distortions and impact our conclusions, so we repeat our main analysis with non-seasonality-adjusted data. We find that qualitatively the results hold - urban areas are more impacted than rural, and both have a rapid recovery after the lockdown but still remain below the pre-pandemic levels in most of the post-lockdown phase. The distributional analysis with deciles also portrays a similar pattern as with seasonally adjusted data. Lower deciles experience sharper falls and quicker recovery, while top deciles have smaller fall in lockdown but muted recovery (Figures available on request).

7   Shortcomings of CPHS data

CPHS provides high-frequency, nationally-representative, longitudinal survey data on a range of topics. But its sampling methodology, survey instrument, and the claim of national representativeness have been questioned (Drèze and Somanchi, 2021; Somanchi, 2021; Pais and Rawal, 2021). Several differences in the sampling methodology lead to

the sample being significantly different from the other official nationally-representative surveys. This might impact any analysis using the data (including ours), and there have been some recent efforts toward reweighting the CPHS data (Sinha Roy and Van Der Weide, 2022). In this section, we discuss some of these concerns, and the implications they might have on the results presented so far.

There are several differences in the sampling methodology between CPHS and the nationally-representative surveys conducted by the National Sample Survey (NSS) (Sinha Roy and Van Der Weide, 2022; Dreze and Somanchi, 2021). One consequential difference is that while selecting households within a village, CPHS does not list all households but instead selects every Nth household in each village starting from the main street in the village. This might lead to under-representation of the poorer and marginalized households that are likely to reside in the outskirts (Drèze and Somanchi, 2021). Somanchi (2021) shows that women, young children and illiterate are under represented in the CPHS sample as compared to NSS samples. Somanchi (2021) also finds that the composition of CPHS itself was changing over time. Between 2016 and 2020, the bias against the poor and uneducated grew significantly. CMIE maintains that CPHS is nationally representative even with these differences (Vyas, 2021).

Comparison of CPHS data with other official nationally-representative data also indicates substantive differences in employment and income statistics. Abraham and Shrivastava (2019) find that CPHS substaintially underestimates women's labour force participation rate. They estimate that while the difference in men's labour force participation rate between CPHS and PLFS is only 5 percent, women's labour force participation is underestimated by 40 percent in CPHS as compared to PLFS. Jha and Basole (2022) find that individual income levels are higher in CPHS than in PLFS for 2018-19. At the all-India level, CPHS average is 29 percent higher than that in PLFS. The difference is higher in the rural sector at 46 percent, and at 13 percent for the urban sector (Figure A13).

Sinha Roy and Van Der Weide (2022) attempt to address the differences in instrument design as well as those in sampling design by undertaking a reweighting exercise on the CPHS data. The exercise relies on other nationally-representative survey data in the

same year to reweight the CPHS data. Since no nationally representative data is available for any years beyond 2019, adjusted weights are not available for 2020 or 2021. So we cannot use the re-weighting to check robustness of our results.

As has also been mentioned in the introduction, there was a sharp drop in the households that CMIE managed to interview during the lockdown months, reflected in the significantly lower response rates. Further, as the survey moved from an in-person format to a telephonic mode, it is highly likely that this shift entailed missing the poorest of the households on account of lack of phones, lack of money for recharging the mobile phones, etc. Several purposive surveys during the lockdown have documented the large impacts on the informal economy and the poor as compared to the better off (University, 2020; Basole et al., 2021). If CPHS under-represents the informal economy, then our estimates of regressive impacts during the lockdown would be an underestimate. Wealthy households typically are not captured in *any* household survey. These two combined together - absence of the poorest and the richest segments of the economy - suggests that our results are likely to be conservative estimates of the extent of poverty and inequality changes.

8 Conclusion

While the Covid-19 pandemic is foremost a health crisis, the economic impact of the pandemic on livelihoods, incomes, inequality, and poverty cannot be overemphasized. This study uses high-frequency data from household surveys to estimate the impact of the pandemic on income levels, income inequality, and poverty. Households experienced significant drop in incomes during the lockdown, which has not fully recovered even twenty-two months after the start of the pandemic. The entire income distribution has shifted to the left, leading to an increase in poverty levels in the post-lockdown phase. Inequality increased during the lockdown, but has returned to pre-pandemic levels in the post-lockdown phase.

Income of the lower deciles saw a sharp decline in the lockdown but were quick to recover. On the other hand, the upper deciles experienced smaller initial shock from the

lockdown but recovery has been slow and incomplete. This pattern is due to the different occupation mix amongst the lower and the upper quantiles. Contact-intensive and less secure occupations (populated by the lower quantiles), saw larger drops and quicker recovery. More formal and secure occupations (dominated by the upper quantiles), saw comparatively smaller losses initially but have been slow to recover. The sharpest decline in incomes during the pandemic have been associated with the nationwide lockdown rather than the two Covid infection waves. The economic impact during the peak of the Covid waves has been relatively milder in terms of the income declines.

It also must be stated that even with its potential limitations, CPHS has allowed researchers to answer pertinent and critical questions during these times of crisis. Due to the lack of alternate data over this period, we attempt to use all available knowledge about the CPHS to put caveats to our results, allowing one to make informed policy decisions on the basis of these findings.

Table 1: Percentage of individuals below various poverty lines in various cumulative periods

	Pre-Covid	Lockdown	Post-Lockdown	Second Wave	Post-Second Wave
National Minimum Wage					
Rural (Rs. 2900 PC per month)	32.27	62.32	41.04	45.99	35.80
Urban (Rs. 3344 PC per month)	17.83	55.88	27.93	34.60	24.11
Seventh Pay Commission Minimum Wage					
Rural (Rs. 7000 PC per month)	85.87	90.91	90.48	89.08	87.29
Urban (Rs. 7000 PC per month)	63.73	81.83	73.14	74.79	70.82
World Bank International Poverty Line $2 PPP					
Rural (Rs. 1281 PC per month)	1.13	28.69	3.94	8.75	4.70
Urban (Rs. 1281 PC per month)	0.08	21.16	0.73	2.35	0.45

Note: The table presents the percentage of individuals who live in households that earn less than different income thresholds on a per-capita basis in rural and urban areas. The thresholds are all defined in constant Jan 2020 terms. Pre-Pandemic refers to period from January 2019 to February 2020, Lockdown refers to period from March 2020 to May 2020, post-lockdown refers to period from June 2020 to March 2021, Second wave refers to period from April 2021 and June 2021 and post-second wave refers to period from July 2021 to December 2021.

Table 2: Income Inequality Measures by Pandemic Periods

Period	Mean	Median	Gini	GE(0)	GE(2)	P90P10
Rural						
Pre-Covid	4655	3390	0.44	0.39	0.88	6.82
Lockdown	3751	2534	0.51	0.51	0.94	20.80
Post-Lockdown	3928	2985	0.45	0.39	0.63	14.98
Second Wave	4400	2890	0.49	0.47	0.85	8.89
Post-Second Wave	4455	3394	0.44	0.37	0.61	10.50
Urban						
Pre-Covid	7724	5482	0.41	0.30	0.46	6.24
Lockdown	5572	3913	0.46	0.38	0.53	9.76
Post-Lockdown	5884	4321	0.41	0.29	0.41	6.11
Second Wave	5960	4344	0.39	0.27	0.37	5.74
Post-Second Wave	6168	4648	0.37	0.24	0.32	5.04

Note: The table presents various distribution and inequality statistics for different time periods. Pre-Pandemic refers to period from January 2019 to February 2020, Lockdown refers to period from March 2020 to May 2020, Post-Lockdown refers to period from June 2020 to March 2021, Second wave refers to period from April 2021 and June 2021 and Post-Second wave refers to period from July 2021 to December 2021.

Table 3: Distribution of Occupation Categories within each Income Quintile in Rural Sector

	Quintile 1	Quintile 2	Quintile 3	Quintile 4	Quintile 5	% in Total Population
Wage Labour	29.75	22.61	17.79	13.92	7.41	18.65
Agricultural Labour	8.94	10.44	10.71	10.52	6.7	9.14
Entrepreneur	14.2	17.19	17.2	17.43	15.33	16.3
Small Farmer	30.23	27.2	26.05	22.03	17.65	23.62
Retired	4.19	4.38	4.95	5.3	7.1	5.21
Formal	6.56	9.95	11.48	14.25	21.58	13.46
Big Farmer	6.12	8.23	11.82	16.54	24.22	13.61
Total	100	100	100	100	100	100

Note: The table gives the average share of different household occupation groups in each income quintile in the rural areas between Mar'19 and Feb'20. Table A2 in the appendix gives a detailed discussion on the creation of the occupation groups. Income quintiles are based on a one-year average household income to smooth the month-to-month fluctuations in incomes.

Figure 1: Pandemic Phases, Infection and Mobility Rates
Note: Data Source Ritchie et al. (2020)

Figure 2: Average Monthly Household Per-Capita Income (Without Seasonality Adjustment)

Note: The figure plots the average real monthly per capita household income for all-India, and rural and urban sectors between Jan'18 and Dec'21. The income levels are not seasonally adjusted.

Figure 3: Distribution of Income for Various Time Periods

(a) Rural
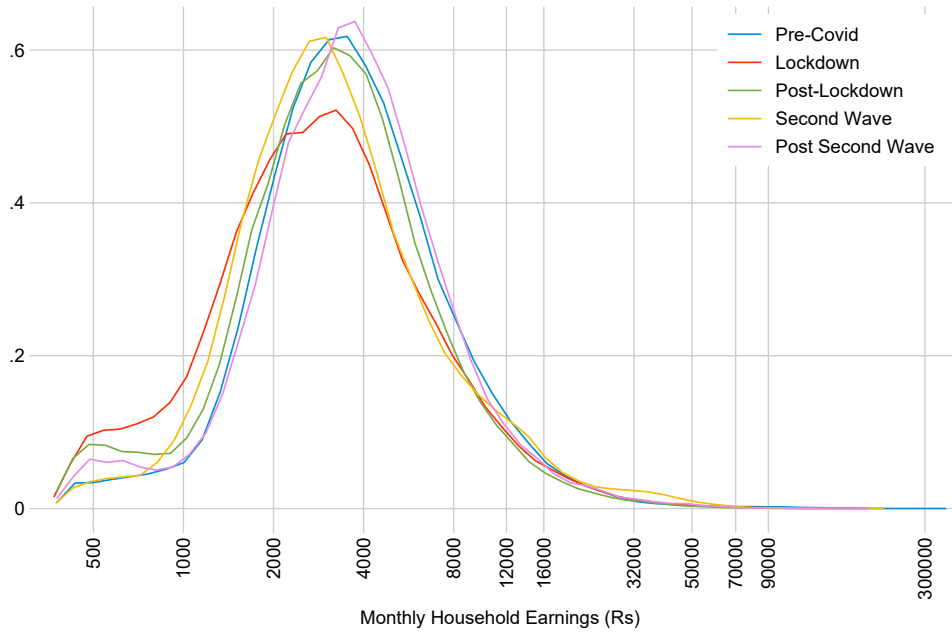

(b) Urban
Note: The above figure are kernel density plots of average per capita household income for each percentile for the different periods. Pre-Pandemic refers to period from January 2019 to February 2020, Lockdown refers to period from March 2020 to May 2020, post-lockdown refers to period from June 2020 to March 2021, Second wave refers from April 2021 and June 2021 and post-second wave refers to July 2021 to December 2021.

Figure 4: Growth Incidence Curves

(a) Rural
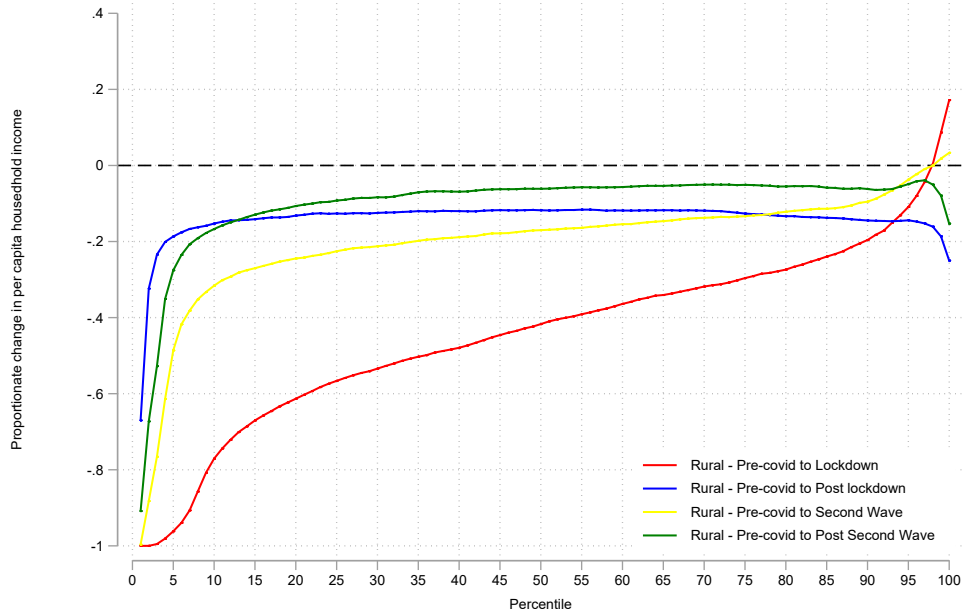

(b) Urban
Note: The above figure plots the proportionate change in average per capita household income for each percentile between the different periods. Pre-Pandemic refers to period from January 2019 to February 2020, Lockdown refers to period from March 2020 to May 2020, post-lockdown refers to period from June 2020 to March 2021, Second wave refers from April 2021 and June 2021 and post-second wave refers to July 2021 to December 2021.

Figure 5: Change in Average Monthly Household Per-Capita Income by Region
Note: The graph plots the proportionate change in per capita seasonally adjusted income estimated separately for rural and urban areas using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure 6: Change in Average Seasonally Adjusted Monthly Household Per-Capita Income vis-a-via February 2020 by Income Deciles

(a) Rural

(b) Urban

Note: The graph plots the percentage change in per capita seasonally adjusted income estimated separately for rural and urban areas using Equation 1 for each income decile. Households are classified into income deciles in each month separately based on their per capita incomes in that month. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. Refer to Tables A9 and A10 in the Appendix for the absolute monthly income levels and the corresponding confidence levels.

Figure 7: Change in Average Seasonally Adjusted Monthly Household Per-Capita Income vis-a-via Predicted Incomes by Income Deciles
(a) Rural

(b) Urban

Note: The graph plots the percentage change in per capita seasonally adjusted income estimated separately for rural and urban areas using Equation 2 for each income decile. Households are classified into income deciles in each month separately based on their per capita incomes in that month. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. Refer to Tables A11 and A12 in the Appendix for the absolute monthly income levels and the corresponding confidence levels.
Figure 8: Change in Average Monthly Household Per-Capita Income by Caste
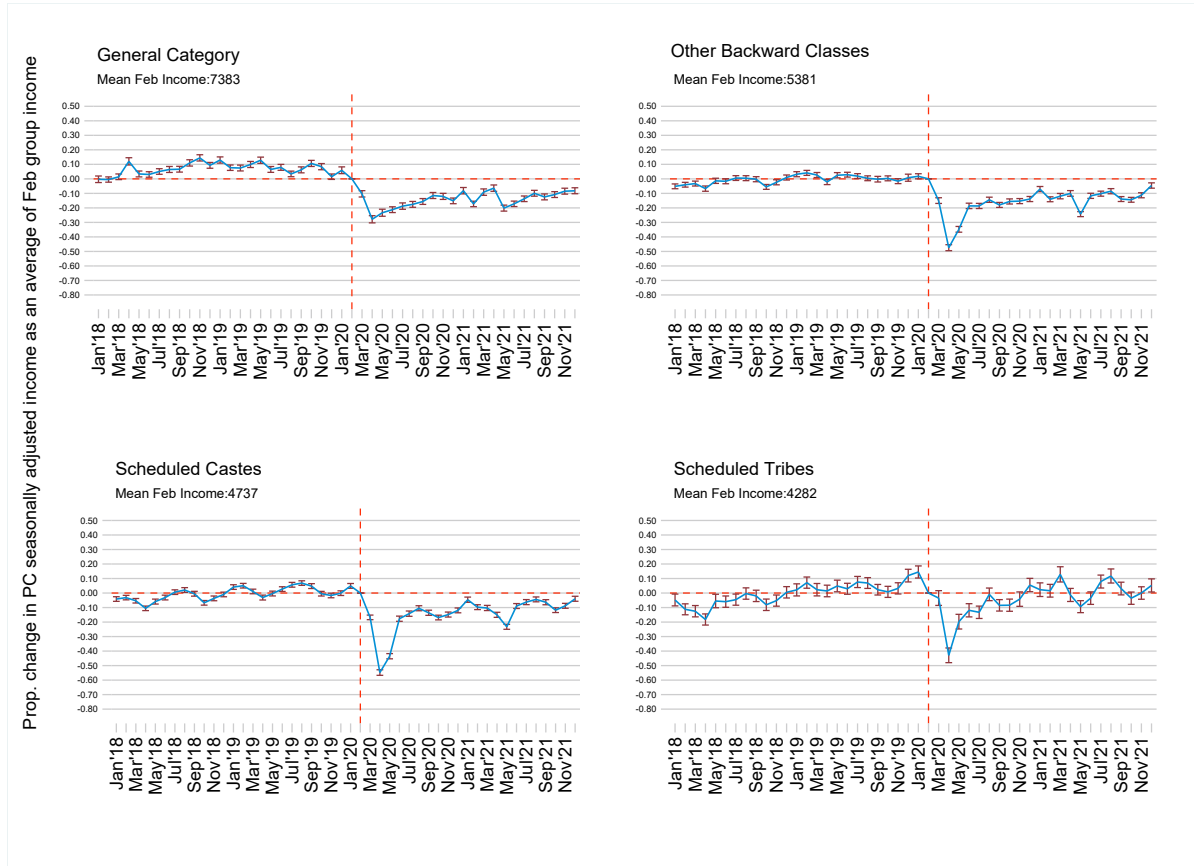

Notes: The graphs plot the proportionate change in per capita seasonally adjusted income estimated separately for the four caste categories using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure 9: Change in Average Monthly Household Per-Capita Income by Religion
Note: The graph plots the proportionate change in per capita seasonally adjusted income estimated separately for Hindus and Muslims using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure 10: Change in Average Monthly Household Per-Capita Income by States Grouped by HDI
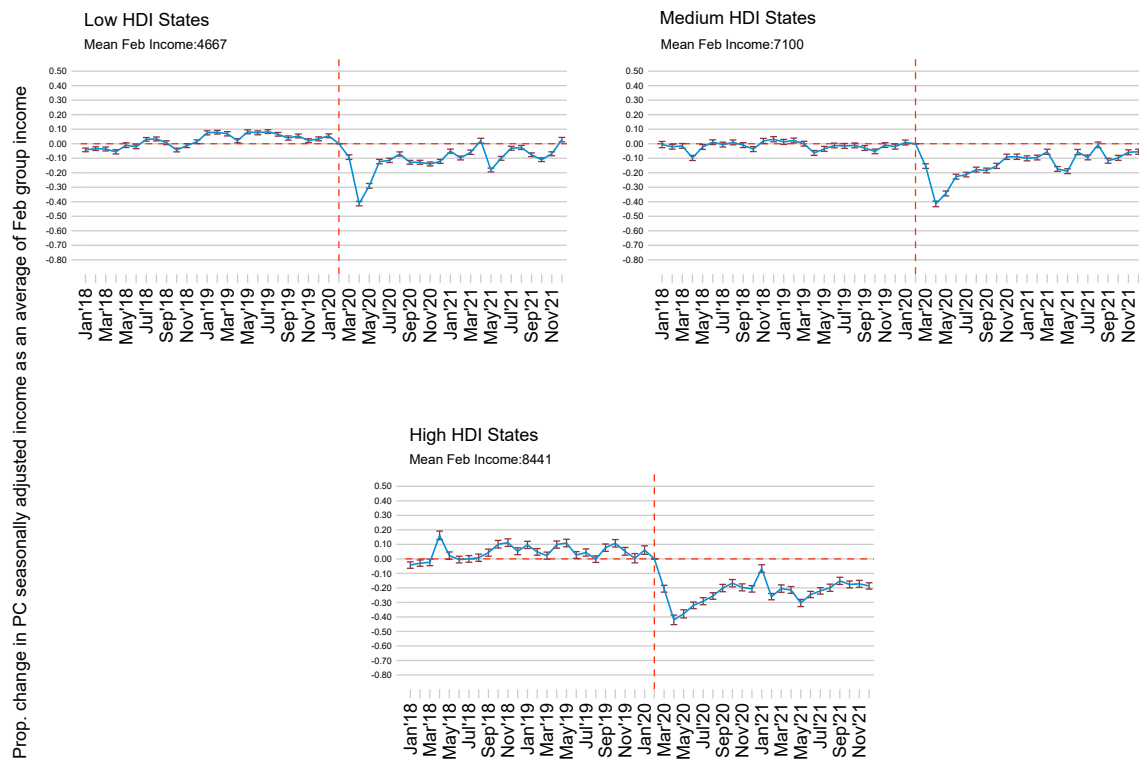

Note: The graph plots the proportionate change in per capita seasonally adjusted income estimated separately for states with low, medium, and high HDI using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure 11: Change in Average Monthly Household Per-Capita Income by Percent of Migrants in States
Note: The graph plots the proportionate change in per capita seasonally adjusted income estimated separately for states with low and high proportion of migrant population using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Table A1: Distribution of caste, religion, sector, and family size by waves

|		w1'19	w2'19	w3'19	w1'20	w2'20	w3'20	w1'21	w2'21	w3'21

Household Size	Mean size	4	4.1	3.9	3.8	3.8	3.8	3.8	3.8	3.7

Note: The table presents the distribution of households by caste category, religion, region of residence (rural/urban) over waves between 2019 and 2021. It also reports the average household size over waves. w1'19 is the first wave of 2019 (Jan'19-Apr'19), w2'19 is the second wave of 2019 (May'19-Aug'19), and w3'19 is the third wave of 2019 (Sep'19-Dec'19). Similarly for the years 2020 and 2021.

Table A2: Classification of Occupation Categories

Rural

Aggregated Occupation Groups	CPHS Household Occupation Group
Agricultural Labourers	Agricultural Labourers
Wage Labourers	Wage Labourers
Enterpreneurs	Entrepreneurs
	Home-based Workers
	Self-employed Entrepreneurs
	Small Traders/Hawkers
	Miscellaneous
Retired/Aged	Retired/Aged
Small/Marginal Farmers	Small/Marginal Farmers
Organised Farmers	Organised Farmers
Formal	Support Staff
	White-collar Clerical Employees
	White-collar Professional Employees
	Business & Salaried Employees
	Industrial Workers
	Legislators/Social Workers/Activists
	Managers/Supervisors
	Non-industrial Technical Employees
	Qualified Self-employed Professionals

Urban

Aggregated Occupation Groups	CPHS Household Occupation Group
Agriculture	Agricultural Labourers
	Organised Farmers
	Small/Marginal Farmers
Wage Labourers	Wage Labourers
	Miscellaneous
Entrepreneurs	Entrepreneurs
	Self-employed Entrepreneurs
	Small Traders/Hawkers
Industrial Workers	Home-based Workers
	Industrial Workers
Support/Non-technical employees	Non-industrial Technical Employees
	Support Staff
Retired/Aged	Retired/Aged
Formal White Collar	White-collar Clerical Employees
	White-collar Professional Employees
	Qualified Self-employed Professionals
	Legislators/Social Workers/Activists
	Managers/Supervisors
	Business & Salaried Employees

We use the household occupation groups in CMIE-CPHS to re-categorize occupations according to the nature and/or extent of their formality[a], and their contact-intensiveness[b]. Since the categories are broad the matching is not perfect, but we try to keep them meaningful. The classification is done separately for the rural and urban sectors.

---

[a]Formal, less formal, informal.

[b]Less face-to-face contact versus more face-to-face contact

Table A3: Percentage of Individuals below Various Poverty Lines in Select Months

	Jan 2019	Apr 2019	Nov 2019	Jan 2020	Apr 2020	Nov 2020	Jan 2021	Apr 2021	Nov 2021
National Minimum Wage									
Rural (Rs. 2900 PC per month)	42.27	46.79	42.86	40.00	73.49	52.52	44.13	52.96	44.85
Urban (Rs. 3344 PC per month)	22.31	24.08	21.92	24.18	66.71	30.26	26.78	32.90	25.96
Seventh Pay Commission Minimum Wage									
Rural (Rs. 7000 PC per month)	84.62	86.68	85.21	83.37	91.31	88.53	86.20	87.35	86.95
Urban (Rs. 7000 PC per month)	62.90	64.38	65.36	65.77	84.92	73.00	70.55	73.89	70.62
World Bank International Poverty Line $2 PPP									
Rural (Rs. 1281 PC per month)	12.26	11.89	11.41	14.11	53.95	16.55	16.00	16.59	14.47
Urban (Rs. 1281 PC per month)	1.39	1.43	1.45	1.84	48.20	1.73	1.63	2.50	1.47

Note: The table presents the percentage of individuals who live in households that earn less than different income thresholds on a per-capita basis in rural and urban areas.

Table A4: Poverty by caste and periods

Period	Intermediate Caste	OBC	SC	ST	General Category	Total
Pre-Covid						
Rural	16.0	33.9	38.9	37.5	30.6	32.9
Urban	6.1	21.3	24.7	28.4	13.4	18.3
Lockdown						
Rural	44.1	65.6	71.7	61.1	55.8	62.8
Urban	36.7	61.4	66.4	64.3	47.7	56.1
Post-Lockdown						
Rural	23.9	42.9	47.8	44.5	41.2	41.7
Urban	12.5	32.3	36.9	33.1	22.6	28.4
Second Wave						
Rural	31.2	47.6	54.4	47.9	44.8	46.9
Urban	18.4	38.3	46.7	46.1	27.8	35.1
Post-Second Wave						
Rural	22.2	38.3	41.3	39.9	34.2	36.8
Urban	11.6	27.3	33.7	33.2	18.6	24.6

Note: The table presents the percentage of individuals who live in households that earn less than the national minimum wage (In Jan 2020 terms these amount to Rs. 2900 per capita in rural areas and Rs. 3344 per capita in urban areas) belonging to different caste categories. CMIE-CPHS reports a distinct caste category of Intermediate Castes, ranked between General Category and Other Backward Classes. Pre-Pandemic refers to period from January 2019 to February 2020, Lockdown refers to period from March 2020 to May 2020, Post lockdown refers to period from June 2020 to March 2021, Second wave refers from April 2021 and June 2021 and Post Second wave refers to July 2021 to December 2021.

Table A5: Poverty by Religion

Period	Hindu	Muslim	Others	Total
Pre-Covid				
Rural	33.0	42.5	8.1	32.2
Urban	17.7	28.1	5.7	18.0
Lockdown				
Rural	62.8	75.2	45.1	62.4
Urban	55.7	71.3	42.6	56.3
Post Lockdown				
Rural	42.3	51.1	15.7	41.2
Urban	28.0	39.3	13.0	28.3
Second Wave				
Rural	47.1	59.3	22.5	46.4
Urban	33.9	51.9	20.8	34.9
Post Second Wave				
Rural	37.5	40.8	12.4	36.1
Urban	24.2	33.0	10.0	24.2

Note: The table presents the percentage of individuals who live in households that earn less than the national minimum wage (In Jan 2020 terms these amount to Rs. 2900 per capita in rural areas and Rs. 3344 per capita in urban areas) belonging to different religions. Other religion includes individuals who report themselves as Buddhist, Christian, Jain, Khasi, Sikh and other religions. Pre-Pandemic refers to period from January 2019 to February 2020, Lockdown refers to period from March 2020 to May 2020, Post lockdown refers to period from June 2020 to March 2021, Second wave refers from April 2021 and June 2021 and Post Second wave refers to July 2021 to December 2021.

Table A6: Poverty by State HDI Groupings

Period	Low HDI	Medium HDI	High HDI	Total
Pre-Covid				
Rural	39.4	21.2	6.2	28.6
Urban	27.1	12.6	7.0	18.8
Lockdown				
Rural	66.8	53.4	50.2	61.1
Urban	65.1	47.1	49.9	58.0
Post Lockdown				
Rural	50.0	27.3	14.6	37.7
Urban	42.2	17.3	20.3	30.5
Second Wave				
Rural	53.1	31.7	25.9	42.6
Urban	46.5	20.4	31.1	36.0
Post Second Wave				
Rural	44.3	22.0	9.9	32.2
Urban	35.6	14.9	15.5	25.5

Note: The table presents the percentage of individuals who live in households that earn less than the national minimum wage (In Jan 2020 terms these amount to Rs. 2900 per capita in rural areas and Rs. 3344 per capita in urban areas). Refer to footnote 17 for the list of states in each group. Pre-Pandemic refers to period from January 2019 to February 2020, Lockdown refers to period from March 2020 to May 2020, Post lockdown refers to period from June 2020 to March 2021, Second wave refers from April 2021 and June 2021 and Post Second wave refers to July 2021 to December 2021.

Table A7: Poverty by Migration Status of States

Period	Out Migration States	In Migration States	Total
Pre-Covid			
Rural	41.1	15.6	29.5
Urban	28.2	10.8	19.2
Lockdown			
Rural	67.7	53.4	61.9
Urban	65.3	49.4	58.0
Post Lockdown			
Rural	51.4	23.5	38.8
Urban	43.5	19.3	31.0
Second Wave			
Rural	54.4	31.0	43.8
Urban	48.4	25.7	36.7
Post Second Wave			
Rural	45.6	18.2	33.2
Urban	37.0	16.0	26.1

Note: The table presents the percentage of individuals who live in households that earn less than the national minimum wage (In Jan 2020 terms these amount to Rs. 2900 per capita in rural areas and Rs. 3344 per capita in urban areas). Refer to footnote 16 for the list of states in each group. Pre-covid refers to time period from Jan 2019 to Feb 2020, lockdown refers to March 2020 to May 2020 and post-lockdown to June 2020 to May 2021.

Table A8: Income Inequality Measures for Select Months

Month	Mean	Median	Gini	GE(0)	GE(2)	P90P10
Rural						
Jan 2019	4660	3389	0.44	0.40	0.93	7.18
Apr 2019	4481	3093	0.46	0.45	1.04	6.71

Observations	446,910	429,112	412,584	409,130	397,848	401,366	402,769	409,431	422,587	412,932

Note: The table gives the proportionate change in incomes for each month as compared to the predicted income in a scenario of no pandemic for that month. Standard errors are clustered at the household level. p<0.01, p<0.05, p<0.1
Figure A2: Change in Average Monthly Household Per-Capita Income vis-a-via Predicted Incomes by Region
Note: The figure plots the change in average real monthly per capita seasonally adjusted household income for rural and urban sectors between Jan'18 and Dec'21, vis-a-via predicted incomes.
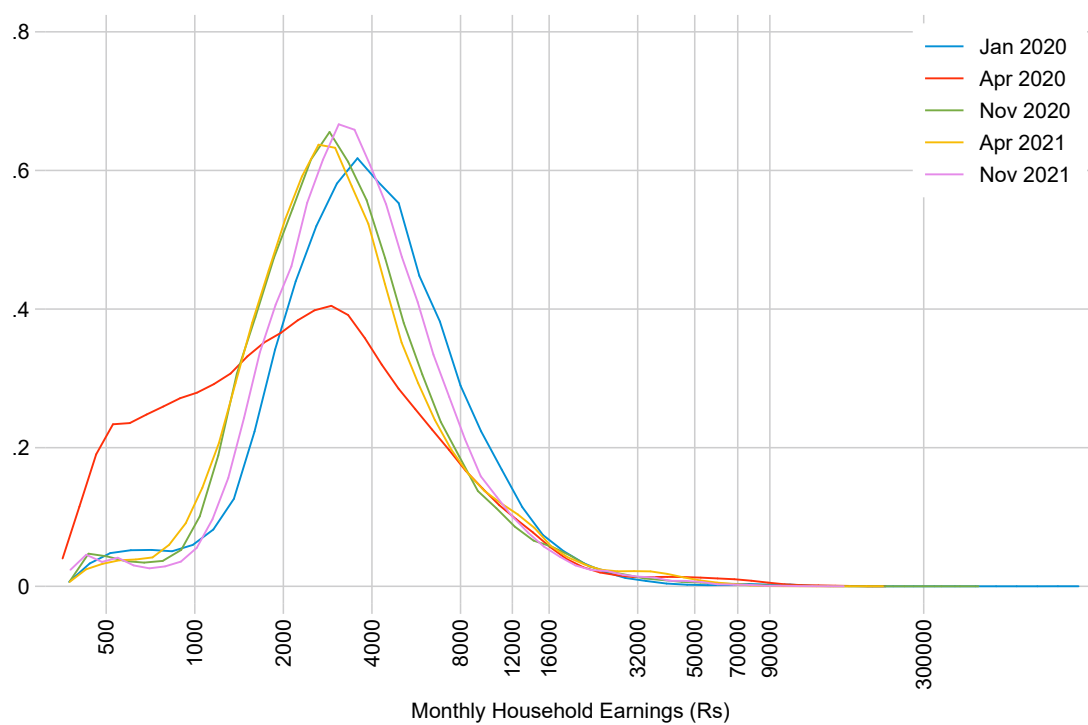

Figure A3: Seasonally Adjusted Average Monthly Household Per-Capita Income

Note: The figure plots the average real monthly per capita seasonally adjusted household income for all- India, and rural and urban sectors between Jan'18 and Dec'21.

Figure A4: Distribution of Income for Select Months

(a) Rural

Monthly Household Earnings (Rs)

(b) Urban

Monthly Household Earnings (Rs)

Note: The above figure are kernel density plots of average per capita household income for each percentile for the select months.

Figure A5: Change in Rural Average Monthly Household Per-Capita Income by Caste
Note: The graph plots the proportionate change in per capita income estimated separately for the different caste categories in the rural sector using Equation 1. The estimates give the change in seasonally adjusted monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure A6: Change in Urban Average Monthly Household Per-Capita Income by Caste
Note: The graph plots the proportionate change in seasonally adjusted per capita income estimated separately for the different caste categories in the urban sector using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure A7: Change in Rural Average Monthly Household Per-Capita Income by Religion

Note: The graph plots the proportionate change in per capita income estimated separately for Hindus and Muslims in the rural sector using Equation 1. The estimates give the change in seasonally adjusted monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure A8: Change in Urban Average Monthly Household Per-Capita Income by Religion
Note: The graph plots the proportionate change in per capita income estimated separately for Hindus and Muslims in the urban sector using Equation 1. The estimates give the change in seasonally adjusted monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.
Figure A9: Change in Rural Average Monthly Household Per-Capita Income by States Grouped by HDI

Note: The graph plots the proportionate change in per capita income estimated separately for low, medium, and high Human Development Index(HDI) in the rural sector using Equation 1. The estimates give the change in seasonally adjusted monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure A10: Change in Urban Average Monthly Household Per-Capita Income by States Grouped by HDI

Note: The graph plots the proportionate change in seasonally adjusted per capita income estimated separately for low, medium, and high HDI in the urban sector using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.
Figure A11: Change in Rural Average Monthly Household Per-Capita Income by Percent of Migrants in States

Note: The graph plots the proportionate change in per capita income estimated separately for the rural sector in states with low and high percentage of migrants using Equation 1. The estimates give the change in seasonally adjusted monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure A12: Change in Urban Average Monthly Household Per-Capita Income by Percent of Migrants in State

Note: The graph plots the proportionate change in seasonally adjusted per capita income estimated separately for the urban sector in states with low and high percentage of migrants using Equation 1. The estimates give the change in monthly per-capita household income as compared to February 2020, after controlling for household fixed effects. The estimates are reported along with their 95% confidence intervals. Standard errors are clustered at the household level.

Figure A13: Distribution of Labour Earnings in CPHS and PLFS
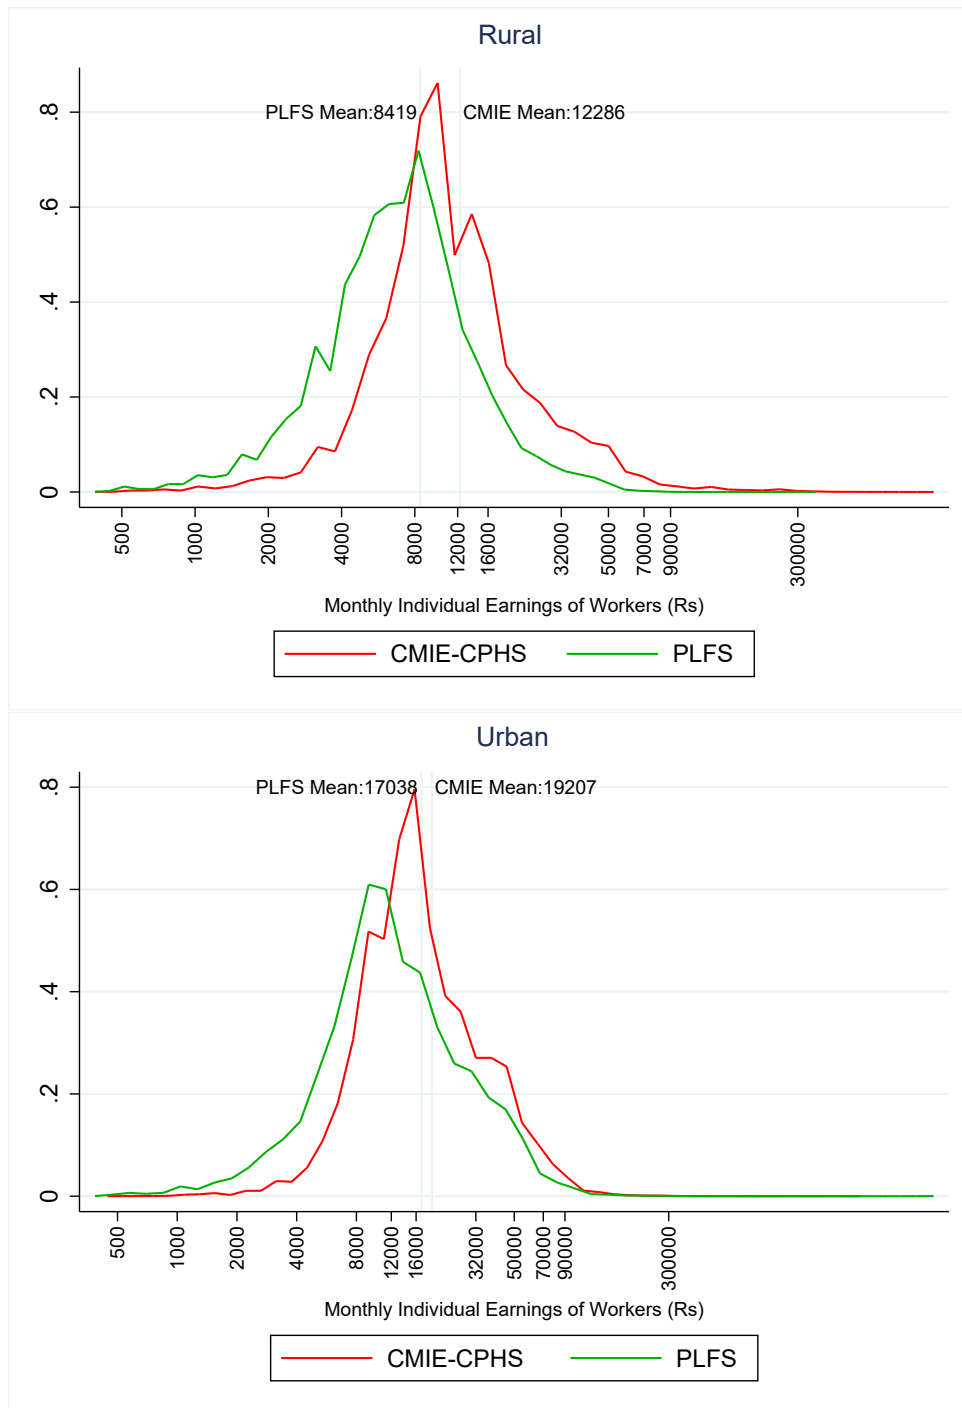

Note: The above figures are kernel density plots of labour earnings in CPHS and PLFS, separately for the rural and urban sectors. (Jha and Basole, 2022)
